### ABSTRACT

In this Letter we present clear evidence that Mrk 573 is an obscured narrow-line Seyfert 1 (NLSy1) galaxy and not an archetypal Seyfert 2, as it has been classified until now. Only three galaxies have been proposed as members of this class, prior to this work. Here we report near-infrared spectroscopic data taken with LIRIS on the 4.2 m William Herschel Telescope (WHT). Our high-quality near-infrared nuclear spectrum in the 0.88–1.35  $\mu\text{m}$  wavelength range shows the permitted O I  $\lambda\lambda$ 1.128, 1.317 narrow lines, the Fe II 9200 Å lines, and the Fe II 1  $\mu\text{m}$  lines, together with a relatively broad component ( $\sim 1700 \text{ km s}^{-1}$ ) of Pa $\beta$ . These features can originate only in an optically thick high-density region, similar to those observed in the broad-line region (BLR).

### 1. INTRODUCTION

The NLSy1 galaxies (Osterbrock & Pogge 1985; Pogge 2000) share the optical properties of Seyfert 1 nuclei, except that they show narrower Balmer lines (FWHM < 2000  $\text{km s}^{-1}$ ) and strong optical Fe II emission. In the X-rays, these objects are also peculiar because of their soft X-ray excess and rapid X-ray variability (Boller et al. 1996; Véron-Cetty et al. 2001), together with a very steep photon spectral index (Leighly 1999). The most accepted explanation for these extreme X-ray properties are high Eddington ratios ( $L/L_{\text{Edd}} \sim 1\text{--}10$ ) and lower black hole masses relative to other Seyfert nuclei ( $M_{\text{BH}} \sim 10^6\text{--}10^7 M_{\odot}$ ) (Mathur et al. 2001; Boroson 2002; Grupe 2004). In addition, Nagar et al. (2002) and Dewangan & Griffiths (2005) suggested the existence of the type 2 counterparts of the NLSy1s, i.e., obscured NLSy1s, which appear as Seyfert 2 galaxies but contain a Seyfert 1 engine characterized by a high accretion rate or a small BH mass. Dewangan & Griffiths (2005) proposed NGC 7582, NGC 5506, and NGC 7314 as obscured NLSy1s, based on their extreme X-ray variability and Compton-thick nature. NGC 5506 was also confirmed as an NLSy1 in the near-infrared by Nagar et al. (2002). This type of objects would be misclassified using only the visible range. They can be distinguished through low-extinction wavelength regimes, for example the near-infrared.

The galaxy Mrk 573 has been extensively studied by many authors. Its active nucleus is hosted in an (R)SAB(rs)0+ galaxy<sup>3</sup> and has been classified until now as a classical type 2 nucleus from previous optical (Tsvetanov & Walsh 1992; Erkers et al. 1997; Mullaney & Ward 2008) and infrared spectroscopic data (Veilleux et al. 1997; Riffel et al. 2006). Spectropolarimetric observations (Nagao et al. 2004) reveal a broad component of the H $\alpha$  profile ( $\sim 3000 \text{ km s}^{-1}$ ), together with the optical Fe II multiplet. Prominent forbidden high-ionization emission lines have also been detected in the optical spectrum

of this galaxy, as for example [Fe VII]  $\lambda$ 0.609 and [Fe X]  $\lambda$ 0.637 (Erkers et al. 1997; Mullaney & Ward 2008). In the X-ray regime this galaxy presents a soft X-ray excess ( $L_{\text{soft}}^{\text{obs}} = 1.6 \times 10^{41} \text{ ergs s}^{-1}$ ) and a steep photon spectral index ( $\Gamma = 2.7 \pm 0.4$ ) (Guainazzi et al. 2005). It also appears as a Compton-thick object ( $N_{\text{H}} > 1.6 \times 10^{24} \text{ cm}^{-2}$ ) and shows a large EW of the K $\alpha$  fluorescent iron line (Guainazzi et al. 2005).

In this Letter we report on new LIRIS near-infrared spectroscopy of Mrk 573, which, together with the X-ray properties of this galaxy, unambiguously identifies it as an obscured NLSy1. This reclassification is based on the detection of the permitted Fe II 9200 Å lines and the Fe II 1  $\mu\text{m}$  lines, together with the O I  $\lambda\lambda$ 1.128, 1.317 transitions and a relatively broad component of the Pa $\beta$  profile. We also report the first detection of a conspicuous line at 0.962  $\mu\text{m}$  that tentatively could be identified as either O I or He I, or as a blend of both transitions.

### 2. OBSERVATIONS AND DATA REDUCTION

High-quality near-infrared long-slit spectra in the range 0.8–2.4  $\mu\text{m}$  were obtained on the night of 2006 July 17 using the near-infrared camera/spectrometer LIRIS (Manchado et al. 2004) on the 4.2 m William Herschel Telescope (WHT). The spatial scale is 0.25" pixel<sup>-1</sup>, and the slit width 0.75" (allowing a spectral resolution in the range  $\sim 600\text{--}400 \text{ km s}^{-1}$ ). The slit was centered on the galaxy nucleus and it was oriented along P.A. = 122°, coincident with the orientation of the ionization cone observed by Pogge & De Robertis (1995). Weather conditions were good, with the seeing varying between 0.8" and 0.9". Observations were performed following an ABBA telescope-nodding pattern. A total exposure time of 4000 s was taken, divided into individual frames of 500 s each. The data were reduced following standard procedures for near-infrared spectroscopy, using the `lirisdr` dedicated software within the IRAF<sup>4</sup> environment. For a detailed description of the reduction process, see Ramos Almeida et al. (2006). The nearby A0 HD 2193 star was observed with the same configuration and similar airmass to the galaxy to perform the telluric cor-

<sup>3</sup> The redshift of the galaxy has been measured at  $z = 0.017$  (Ruiz et al. 2005), which implies a physical scale of 333 pc arcsec<sup>-1</sup>, using  $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$ .

<sup>4</sup> IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for the Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation (<http://iraf.noao.edu/>).

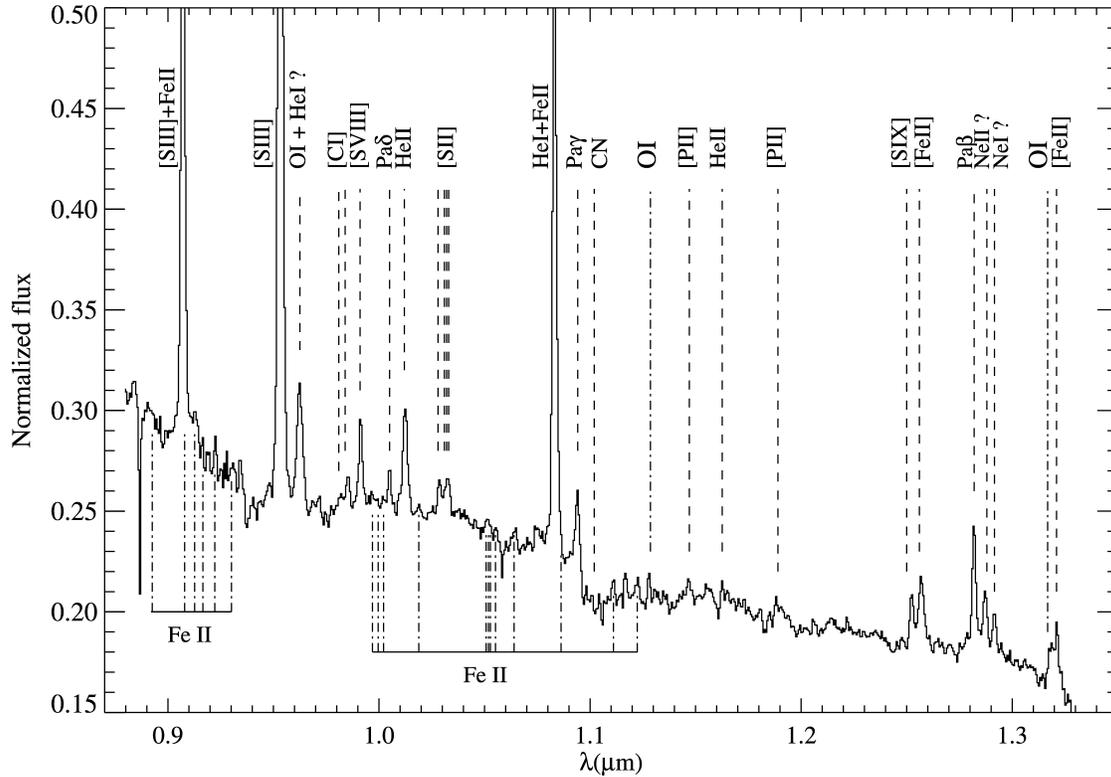

FIG. 1.—Normalized spectrum of the nuclear region of Mrk 573 in the  $ZJ$  range. Detections of the permitted Fe II 9200 Å lines and the Fe II 1  $\mu\text{m}$  lines, together with the O I  $\lambda\lambda$ 1.128, 1.317 lines are clear. Note the broad base of the Pa $\beta$  profile.

rection and the flux calibration. A modified version of Xtelcor (Vacca et al. 2003) was used in this step. Note that the absolute flux calibration is intended to be an approximation since the spectrum of the comparison star is probably subject to centering and tracking errors, as well as slit losses.

### 3. RESULTS

The final nuclear spectrum, extracted with a 1.5'' aperture centered on the maximum of the galaxy profile, is shown in Figure 1. Most detected lines are marked in the figure, and their fluxes and FWHMs (measured by fitting a Gaussian profile using the Starlink program DIPSO) are reported in Table 1. In general terms, the spectrum is typical of a Seyfert 2 galaxy, showing very high ionization lines such as [S VIII]  $\lambda$ 0.991 and [S IX]  $\lambda$ 1.252. One can also note the presence of the 1.1  $\mu\text{m}$  CN band, first reported for this galaxy by Riffel et al. (2007), that shows the existence of young/intermediate stars in the nuclear region. The main focus of this Letter is on the detection

NOTE.—Lines whose FWHM values are not shown are narrower than the instrumental profile.

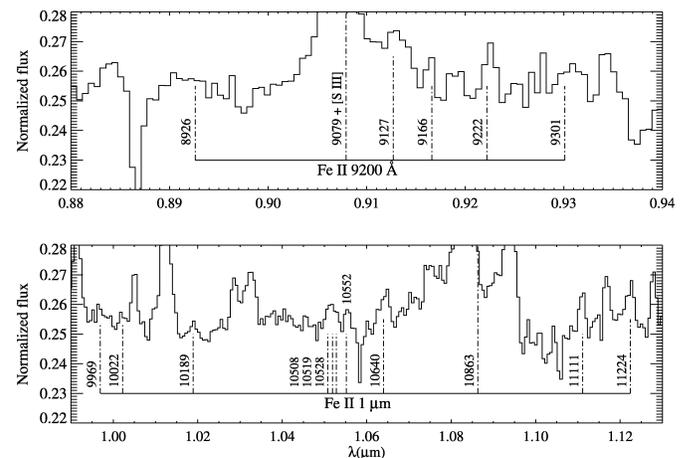

FIG. 2.—Detailed view of the nuclear spectrum of Mrk 573 around the permitted Fe II 9200 Å lines and the Fe II 1  $\mu\text{m}$  lines.

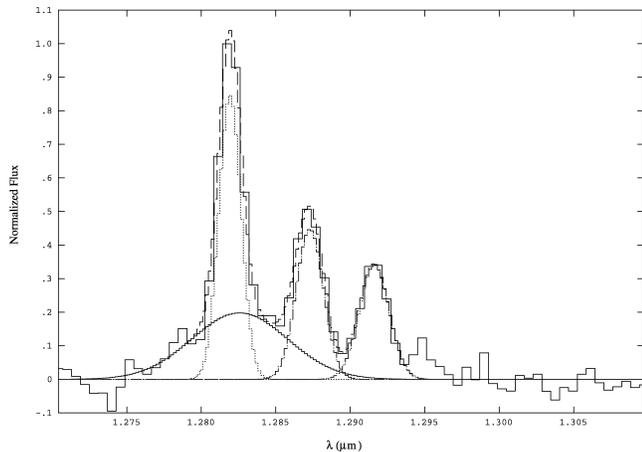

FIG. 3.—Detailed view of the nuclear spectrum of Mrk 573 around the Pa $\beta$  line. The narrow and intermediate components are represented, together with the Gaussian profiles of the two unidentified lines, at 1.287 and 1.292  $\mu\text{m}$ , respectively. [See the electronic edition of the *Journal* for a color version of this figure.]

of the permitted O I and Fe II lines well above the noise level, and of the broad wings of the Pa $\beta$  profile.

The O I  $\lambda\lambda$ 1.128, 1.317 permitted transitions are produced by Ly $\beta$  pumping in a Bowen fluorescence mechanism (Grandi 1980), and they are only produced in a high-density optically thick gas. Thus, these lines are seen only in Seyfert 1 or NLSy1 nuclei, but never in canonical Seyfert 2 galaxies.

In Figure 2 all the detected Fe II transitions are labeled for both the Fe II 9200 Å lines (0.893, 0.908, 0.913, 0.917, 0.922, and 0.930  $\mu\text{m}$ ), and the Fe II 1  $\mu\text{m}$  lines (0.997, 0.999, 1.002, 1.019, 1.051, 1.052, 1.053, 1.055, 1.064, 1.086, 1.111, and 1.122  $\mu\text{m}$ ). Very few Seyferts with near-infrared detection of permitted Fe II lines have been reported until now in the literature (Rudy et al. 2000, 2001; Nagar et al. 2002; Rodríguez-Ardila et al. 2002b, 2005). The detection of Fe II lines provides crucial information on the ionization mechanism of the gas, since they are thought to be pumped by Ly $\alpha$  fluorescence (Johansson & Jordan 1984; Sigut & Pradhan 2003) and they can be formed only in high-density clouds or in the optically thick BLR.

For Mrk 573, we estimate the line width of O I  $\lambda$ 1.317 to be FWHM  $\sim$  320  $\text{km s}^{-1}$ , which is practically the same as the narrow component of the recombination lines (see Table 1). For NLSy1s the widths of the O I and Fe II lines do not necessarily have to be comparable to the broad component of the recombination lines. For example, in the case of Mrk 335, the Pa $\beta$  FWHM = 2050  $\text{km s}^{-1}$ , while the O I  $\lambda$ 1.128 FWHM = 1100  $\text{km s}^{-1}$  (Rodríguez-Ardila et al. 2002a). More dramatic is the case of Ark 564, another typical NLSy1, for which the Pa $\beta$  FWHM = 1800  $\text{km s}^{-1}$  while the O I  $\lambda$ 1.128 FWHM = 600  $\text{km s}^{-1}$  (Rodríguez-Ardila et al. 2002a).

A relatively broad component of the Pa $\beta$  profile with FWHM  $\sim$  1700  $\text{km s}^{-1}$  is detected, in addition to the narrow component (see Fig. 3 and Table 1). This line width is smaller than the reported by Nagao et al. (2004) for the optical hydrogen recombination lines in polarized light. The Pa $\beta$  broad component contains about 50% of the total line flux, which is very similar to the fraction found by Nagar et al. (2002) for the same line in NGC 5506.

Another interesting feature detected in our spectrum is seen at 0.962  $\mu\text{m}$ , very close to the prominent [S III]  $\lambda$ 0.953 line. The former is not detected in previous near-infrared spectra of Mrk 573 (Veilleux et al. 1997; Riffel et al. 2006) and remains unidentified in the literature. The most likely possible identifications of

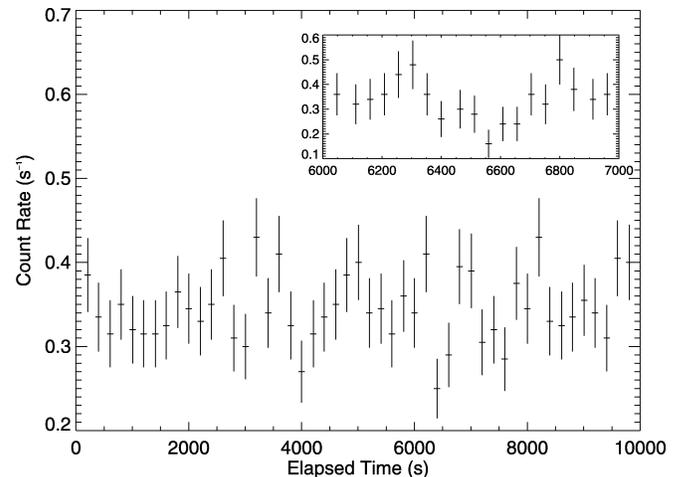

FIG. 4.—The 2–12 keV EPIC-pn light curve of Mrk 573 spanning the full length of the observations with bins of 200 s. The inset represents one of the extreme events with smaller bins of 50 s.

this line are O I ( $3D_0-3D$ ) or He I ( $1P_0-1D$ ).<sup>5</sup> We cannot discard either of the two possibilities, since we detect other O I lines in our near-infrared spectrum, and also, in the optical, He I  $\lambda$ 0.668 ( $1P_0-1D$ ) has been detected (Erkens et al. 1997). It is notable that the FWHM of this line ( $\sim$ 700  $\text{km s}^{-1}$ ) is the broadest in our spectrum (see Table 1) and could be due to line blending. There are another two lines very close to Pa $\beta$  (see Figs. 1 and 3), at 1.287 and 1.292  $\mu\text{m}$ . Tentatively, they are Ne II ( $2D-2P_0$ ) and Ne I,<sup>6</sup> respectively, according to the NIST Atomic Spectra Database.<sup>7</sup> The nondetection in previous near-infrared spectra of all the features mentioned in this section could be due to the higher signal-to-noise of our data, or to a more complex scenario that would allow time variations in the spectrum of Mrk 573.

#### 4. DISCUSSION

The detection in our near-infrared spectra of the permitted Fe II and O I lines, together with the relatively broad component ( $\sim$ 1700  $\text{km s}^{-1}$ ) of Pa $\beta$ , argues against the Seyfert 2 nature of Mrk 573 and fits perfectly the classical definition of NLSy1 galaxies. This is also confirmed by the presence of the optical Fe II multiplet in polarized light (Nagao et al. 2004). The X-ray properties of Mrk 573 are also typical of NLSy1 galaxies: a soft X-ray excess and a steep photon spectral index ( $\Gamma = 2.7 \pm 0.4$ ) (Guainazzi et al. 2005). We have searched for X-ray variability in the publicly available *XMM-Newton* data of this galaxy.<sup>8</sup> The light curve shows variations of the count rates by a factor of  $\sim$ 2 within 300 s (see Fig. 4), which is similar to the variability of NLSy1s (Leighly 1999; Véron-Cetty et al. 2001; Dewangan & Griffiths 2005).

The optical spectra also reveal broad components of the H $\alpha$  and H $\beta$  profiles of  $\sim$ 3000  $\text{km s}^{-1}$  in polarized light (Nagao et al. 2004). These line widths are, in principle, more typical of Sy1 than of NLSy1 galaxies. Nevertheless, very recently, Mul-laney & Ward (2008) found that in order to reproduce the H $\alpha$

<sup>5</sup> Computed with the line identification software package EMILI (Sharpee et al. 2003), which employs an updated version of the ver. 2.04 Atomic Line List.

<sup>6</sup> Ne I ( $2s^2p^5(^2P_{1/2}^o)3p^2[3/2]_2-2s^2p^5(^2P_{3/2}^o)4s^2[3/2]_2^o$ ).

and H $\beta$  profiles of a sample of well-known NLSy1 galaxies they needed three components of different widths (the broadest ones of FWHM  $\geq 3000$  km s $^{-1}$ ). These findings indicate that the limit of FWHM  $< 2000$  km s $^{-1}$  imposed on the definition of NLSy1s (Pogge 2000) is not realistic. Indeed, Mrk 573 shows examples of the three kinematical components in its optical and near-infrared spectra. Thus, there must exist an intermediate high-density region, with intermediate properties between the narrow-line region (NLR) and the BLR, that is producing the observed O I and Fe II lines, together with the relatively broad component of Pa $\beta$ . This intermediate region must be dense enough to produce lines which are broader than the narrow lines, but not as broad as those detected in polarized light.

In “classical” NLSy1 galaxies, both the O I and Fe II permitted lines are normally more prominent (Riffel et al. 2006), although not necessarily broader (Grandi 1980) than in Mrk 573. Moreover, their optical counterparts are also detected (Collin & Joly 2000), which is not the case for this galaxy. These lines must then be produced in the previously mentioned intermediate high-density region, and must be affected by a moderate amount of extinction. More internally, in the BLR, the  $\sim 3000$  km s $^{-1}$  components observed in polarized light (Nagao et al. 2004) should be produced, but it is difficult to see them directly, due to the presence of an obscuring structure. A similar scenario occurs in the NLSy1 Mrk 618, in which the H $\alpha$  profile shows three components: a narrow one of FWHM  $\sim 200$  km s $^{-1}$ , an intermediate one of  $\sim 1700$  km s $^{-1}$ , and a broad component of  $\sim 3200$  km s $^{-1}$  (Mullaney & Ward 2008). For Mrk 573, we would be seeing the narrow and intermediate components, while the broadest one would be obscured. The existence of an obscuring structure is also in agreement with the X-ray spectra being Compton thick based on the large EW of the K $\alpha$  fluorescent iron line (Guainazzi et al. 2005). Indeed, from high spatial resolution color maps, Quillen et al. (1999) reported the presence of a bar of length 2'', together with leading dust lanes and possibly a dusty disk perpendicular to the jet. Guainazzi et al. (2005) claimed that the presence of dust lanes is correlated with X-ray obscuration.

From all the above considerations, we can reclassify the nucleus of Mrk 573 as a hidden NLSy1, a new member of the class proposed by Nagar et al. (2002) and Dewangan & Griffiths (2005). It shares the properties of the class: X-ray variability within similar timescales, steep photon spectral index, high intrinsic absorption column density, and prominent iron K $\alpha$

line. It is also worth mentioning that in the infrared spectrum the Pa $\beta$  profile is very similar to that of NGC 5506, presenting in both cases a broad pedestal (FWHM  $\sim 1800$  km s $^{-1}$ ).

A possible scenario that would explain the observed properties of Mrk 573 would be the existence of a clumpy dusty torus (Nenkova et al. 2002; Hönig et al. 2006; Hönig & Beckert 2007) that at the epoch of the observations was optically thinner, revealing high-density regions capable of producing the O I and Fe II lines, together with the intermediate component of Pa $\beta$ . The clumpy torus model would allow mutations between type 1 and type 2 objects, as for NGC 7582 (Aretxaga et al. 1999), which is one of the three objects classified by Dewangan & Griffiths (2005) as an obscured NLSy1. This scenario would also explain the detection of the permitted O I and Fe II lines, the relatively broad component of Pa $\beta$ , and the unidentified 0.962, 1.287, and 1.292  $\mu$ m features, which were not reported in the Riffel et al. (2006) near-infrared spectrum, obtained in 2003 October.

A more complex revision of this scenario was discussed by Elitzur & Shlosman (2006) in which the clumpy torus would be formed as an outflow or hydromagnetic disk wind. They proposed that the torus disappears when the bolometric luminosity goes below  $10^{42}$  ergs s $^{-1}$ , since the accretion onto the central black hole cannot then sustain the necessary cloud outflow rate. They also predict that for even lower luminosities the BLR would also disappear, due to the suppression of the cloud outflow. Mrk 573 could be near the lower luminosity limit required for the maintenance of the cloud outflow, leading to the eventual demise of the obscuring structure.
